## C<sub>4</sub> plants in the vegetation of Mongolia: their natural occurrence and geographical distribution in relation to climate

Received: 17 March 1999 / Accepted: 1 November 1999

**Abstract** The natural geographical occurrence, carbon assimilation, and structural and biochemical diversity of species with C<sub>4</sub> photosynthesis in the vegetation of Mongolia was studied. The Mongolian flora was screened for C<sub>4</sub> plants by using <sup>13</sup>C/<sup>12</sup>C isotope fractionation, determining the early products of <sup>14</sup>CO<sub>2</sub> fixation, microscopy of leaf mesophyll cell anatomy, and from reported literature data. Eighty C<sub>4</sub> species were found among eight families: Amaranthaceae, Chenopodiaceae, Euphorbiaceae, Molluginaceae, Poaceae, Polygonaceae, Portulacaceae and Zygophyllaceae. Most of the C<sub>4</sub> species were in three families: Chenopodiaceae (41 species), Poaceae (25 species) and Polygonaceae, genus *Calligonum* (6 species). Some new C<sub>4</sub> species in Chenopodiaceae, Poaceae and Polygonaceae were detected. C<sub>4</sub> Chenopodiaceae species make up 45% of the total chenopods and are very important ecologically in saline areas and in cold arid deserts. C<sub>4</sub> grasses make up about 10% of the total Poaceae species and these species naturally concentrate in steppe zones. Naturalized grasses with Kranz anatomy, of genera such as *Setaria*, *Echinochloa*, *Eragrostis*, *Panicum* and *Chloris*, were found in almost all the botanical-geographical regions of Mongolia, where they commonly occur in annually disturbed areas and desert oases. We analyzed the relationships between the occurrence of C<sub>4</sub> plants in 16 natural botanical-geographical regions of Mongolia and their major climatic influences. The pro-

portion of C<sub>4</sub> species increases with decreasing geographical latitude and along the north-to-south temperature gradient; however grasses and chenopods differ in their responses to climate. The abundance of Chenopodiaceae species was closely correlated with aridity, but the distribution of the C<sub>4</sub> grasses was more dependent on temperature. Also, we found a unique distribution of different C<sub>4</sub> Chenopodiaceae structural and biochemical subtypes along the aridity gradient. NADP-malic enzyme (NADP-ME) tree-like species with a salsoloid type of Kranz anatomy, such as *Haloxylon ammodendron* and *Ilijinia regelii*, plus shrubby *Salsola* and *Anabasis* species, were the plants most resistant to ecological stress and conditions in highly arid Gobian deserts with less than 100 mm of annual precipitation. Most of the annual C<sub>4</sub> chenopod species were halophytes, succulent, and occurred in saline and arid environments in steppe and desert regions. The relative abundance of C<sub>3</sub> succulent chenopod species also increased along the aridity gradient. Native C<sub>4</sub> grasses were mainly annual and perennial species from the Cynodonteae tribe with NAD-ME and PEP-carboxykinase (PEP-CK) photosynthetic types. They occurred across much of Mongolia, but were most common in steppe zones where they are often dominant in grazing ecosystems.

**Key words** Mongolia · Climate · Vegetation type · C<sub>4</sub> photosynthesis · Plant distribution

### Introduction

Mongolia occupies a large area, about 1,565,000 km<sup>2</sup> (52°06'–41°32'N, 87°47'–119°54'E). It is primarily a mountain country mixed with steppe, on average 1580 m above sea level, varying from 533 to 4355 m. The relief is very complicated with latitudinal climate zones mixed with altitudinal gradients, particularly in the West. Mongolia is in the center of the Asian continent which leads to an extreme continental climate and very low precipitation. The absolute temperatures vary from –50°C in win-

ter to 40°C in summer. The maximum annual precipitation is near 250–300 mm in the north, or at elevations over 3000 m; decreasing to 100–150 mm in the south, then less than 50 mm in the Transaltai Gobi deserts (Vostokova et al. 1995). Mongolia is the termination of Asia's monsoon climate zone, so about 50–70% of precipitation occurs in summer. Thus, its specific climatic features are aridity in all regions, particularly in southern and western regions, and a continental climate of extreme cold and heat.

Asian ecosystems, particularly continental deserts and mountains, have not been studied in detail for the occurrence of C<sub>4</sub> species and their distribution in relation to climate. The deserts of Asia differ markedly from the arid ecosystems of North America, Australia and Europe in the taxonomic groups of their C<sub>4</sub> species. In Asia Chenopodiaceae is the leading C<sub>4</sub> family and grasses with Kranz anatomy are less important, particularly in arid regions (Pyankov et al. 1986, 1992a; Pyankov and Mokronosov 1993). Several studies have identified C<sub>4</sub> Chenopodiaceae species from the Near East and Central Asia (Shomer-Ilan et al. 1981; Winter 1981; Ziegler et al. 1981; Zalenskii and Glagoleva 1981; Voznesenskaja and Gamaley 1986; Pyankov and Vakhrusheva 1989; Gamaley et al. 1992; Pyankov et al. 1992a, 1997; Akhani et al. 1997). The C<sub>4</sub> syndrome is known in about 250–300 chenopods mostly in Salsoloideae (tribes Suaeadeae and Salsoleae) and Chenopodioideae (tribes Camphorosmeae and Atripliceae); but many species are unclassified. The occurrence of C<sub>4</sub> species has been studied mostly in west Asian deserts, e.g., the Central Karakum desert (Pyankov et al. 1986; Pyankov and Vakhrusheva 1989), in part of Mongolia (Gamaley 1985; Gamaley and Shirevdamba 1988), in South Tadzhikistan (Pyankov and Molotkovskii 1992, 1993), in some regions of the former Soviet Union (Pyankov and Mokronosov 1993), the Pamir mountains (Pyankov 1993; Pyankov and Mokronosov 1993), and in northeast China (Redman et al. 1995). In large regions of Central and East Asia the plant photosynthetic types have not been studied and the climatic pattern of C<sub>4</sub> plant distribution is unknown.

The pioneer works of J.A. Teeri and L.G. Stowe in North America show clear relationships between climatic variables and the relative abundance of C<sub>3</sub> and C<sub>4</sub> plants within Poaceae (Teeri and Stowe 1976), in dicot plants (Stowe and Teeri 1978), and in Cyperaceae (Teeri et al. 1980). Within Poaceae and Cyperaceae the relative abundance of C<sub>4</sub> species in a particular region is strongly correlated with minimum daily temperatures during the growing season ( $r=0.97$ ). In contrast native C<sub>4</sub> dicots showed strong correlations with pan evaporation during summer months ( $r=0.947$ ), annual evaporation ( $r=0.934$ ), and the dryness ratio ( $r=0.931$ ). Their work provides strong evidence that the climatic preferences of C<sub>4</sub> dicots differ from those of C<sub>4</sub> grasses. They concluded that the photosynthetic physiology of C<sub>4</sub> dicots differs from that of C<sub>4</sub> grasses.

More recently, additional information has accumulated on the ecology of C<sub>4</sub> plants, mostly on their occur-

rence and distribution in ecosystems dominated by C<sub>4</sub> grasses in: Africa (Tieszen et al. 1979; Vogel et al. 1978; Batanouny et al. 1988; Schulze et al. 1996), Europe (Doliner and Jolliffe 1979; Collins and Jones 1985; Mateu Andres 1992; Kalapos et al. 1997), Australia (Hattersley 1983), and the Near East (Shomer-Ilan et al. 1981; Vogel et al. 1986). The climatic pattern of C<sub>4</sub> dicot and C<sub>4</sub> monocot distribution over the world has been summarized by Ehleringer et al. (1997).

Other studies have presented new relationships between ecological parameters, photosynthetic types, biochemical subtypes, and taxonomy in Poaceae (Hattersley and Watson 1992) and Cyperaceae (Takeda et al. 1985; Ueno et al. 1986; Ueno and Takeda 1992; Li 1993). Hence "taxonomic" identification of C<sub>4</sub> is possible from the occurrence of species in floristic lists.

The objectives of this study in Mongolia were to identify all the plants with C<sub>4</sub> photosynthesis, and to analyze the geographical distribution patterns of C<sub>4</sub> species, with emphasis upon Poaceae and Chenopodiaceae, as a function of Mongolian climatic variables. We also studied climatic and ecological distribution of C<sub>4</sub> grasses and chenopods with different photosynthesis biochemistry, mesophyll structures, and life forms. Here we demonstrate that C<sub>4</sub> grasses and chenopods differ in their relationship to climatic variables and that morphological and anatomical features are important for survival in various habitats. Such knowledge can be useful in the evaluation and prediction of vegetation changes during global climatic changes, in the conservation and restoration of natural ecosystems, and in improving pastures for the nomadic society based on domestic livestock grazing.

## Methods

### Determination of photosynthetic types

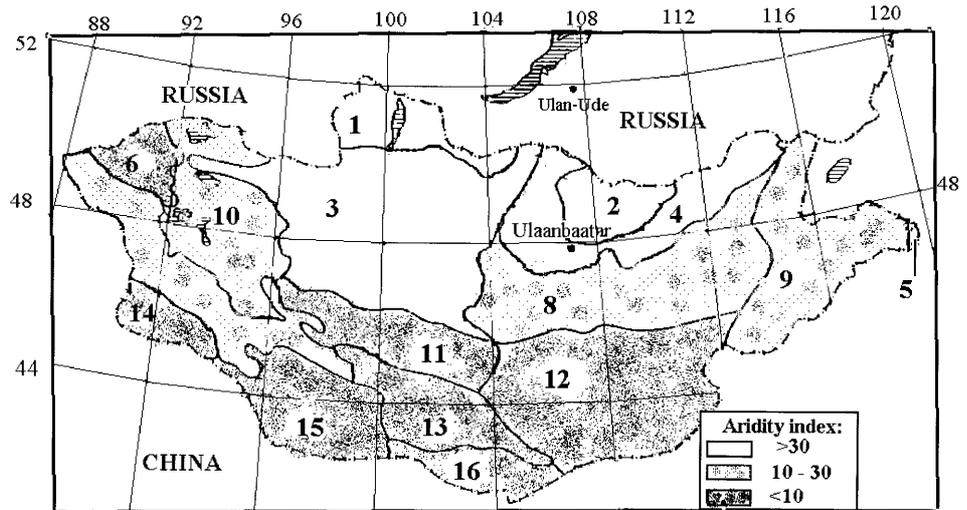

Mongolian plant photosynthetic types were determined from microscopic studies of Kranz anatomy,  $\delta^{13}\text{C}$  fractionation, primary  $^{14}\text{CO}_2$  photosynthetic products, and  $^{14}\text{C}$  turnover. Many experiments were conducted in 1993 during a field expedition, mainly in steppe, semidesert, and desert areas in the following places: Bulgan-Somon (44°06'N, 103°32'E), Shine-Dzhinst (44°33'N, 99°17'E), Ekhin-Gol (43°15'N, 99°00'E) and Gurvantes (43°13'N, 101°03'E).

$\delta^{13}\text{C}$  analysis was performed by standard techniques (Bender et al. 1973) with a United States National Bureau of Standards bicarbonate sample as a standard. Plant photosynthetic tissue samples were field-collected in natural habitats, sun-dried and transported to the USA for  $\delta^{13}\text{C}$  analysis.

The pathway of primary  $^{14}\text{CO}_2$  fixation and turnover was determined from the fixation kinetics during a  $^{14}\text{CO}_2$  pulse (10-s exposure) followed by a chase exposure to  $^{12}\text{CO}_2$  in air (10, 30, 60, and 120 s) with the techniques described in Pyankov et al. (1999). Species with over 50% of  $^{14}\text{C}$  in malate or aspartate after 10 s were classified as either NADP-ME or NAD-ME, respectively.

The assignment to photosynthetic types and biochemical groups was done on the basis of data obtained from our studies, from published works, or from closely related species for grasses (Hattersley and Watson 1992) and for chenopods (Pyankov et al. 1992a, 1997; Akhani et al. 1997).

**Fig. 1** Botanical-geographical regions of Mongolia (Grubov 1982) and their aridity. De Martonne aridity index,  $I=P/T+10$ . [ $P$  annual precipitation (mm),  $T$  average annual temperature ( $^{\circ}\text{C}$ )]

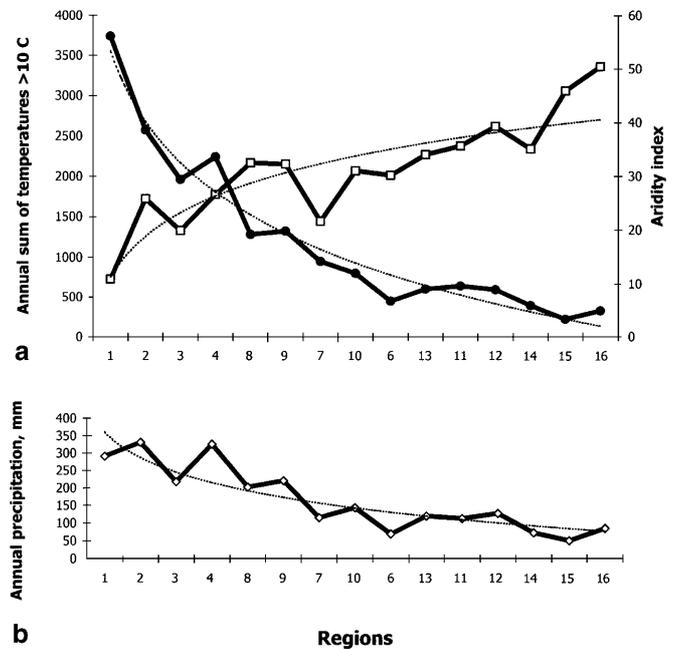

### Geographical distribution, climatic data and plant ecological characteristics

We used the botanical-geographical divisions of Grubov and Junatov (1952), as used in the identification of Mongolian flora (Grubov 1966, 1982; Gubanov 1996). There are 16 botanical-geographical regions in Mongolia (Fig. 1), based on similarity of climatic features (Table 1), environment, and floristic complexes. Data on climatic variables from meteorological stations were obtained from the Ministry of Nature and Environment. Actually there are few meteorological stations in these large regions; therefore the data from individual stations only give general information about the climatic features of each botanical-geographical zones. Figure 2 presents changes the main climatic variables from moist cool regions to extra arid deserts.

Generally, all botanical-geographical regions can be combined into three groups on the basis of orography, climate, soils, and vegetation plus precipitation, temperature, and aridity. The first group (regions 1–5) (Fig. 1) covers northern and western Mongolia, with forest and semisteppe vegetation, with a maximum annual precipitation of 200–350 mm, a low warm-temperature sum, and low aridity (Table 1). The second group (regions 7–10) covers mainly steppe vegetation, with an annual precipitation of 100–200 mm and medium aridity indexes from 30 to 10. The third group (regions 6, 11–16) includes those with the lowest precipitation, the highest summer temperatures, and high aridity. These are the Gobian deserts and dry mountain areas to the west and south. The areas of some botanical-geographical regions are very large, for instance, Khentei (3), Mongolian Altai (7), Middle Khalkha (8), Depression of Great Lake (10), East Gobi (12), and include areas with quite diverse altitudes, climatic subzones and vegetation types. Such data do not allow a detailed analysis of the relationship between the occurrence of different plants and climatic variables; rather we will present the main trends in plant distribution along the major climatic gradients. Region 5 was excluded from analysis, because it is not comparable with other regions in size (Fig. 1) and species number. Recently, a more detailed ecological division of Mongolia that includes 36 regions with more similar climatic and biological features has been proposed (Vostokova et al. 1995) but currently both detailed floristic and climatic data are lacking.

We used the de Martonne aridity index (Oliver and Fairbridge 1987), defined as  $I=P/T+10$ , where  $P$  is the average annual precipitation, and  $T$  is the average annual temperature. The minimum absolute values of this index correspond to the maximum aridity of climate.

Floristic species abundance was obtained from recent lists of Mongolian flora by Gubanov (1996). Habitats for each species were described at the time of collection, or obtained from Grubov (1982).

**Fig. 2** Main climatic parameters for the botanical-geographical regions of Mongolia. The abscissa shows *region numbers* arranged along an aridity gradient. *Solid lines* are average annual parameters for regions; *dotted lines* are their logarithmic approximations

Pearson's correlation coefficients were calculated for the relationships between climatic variables and the occurrences of Chenopodiaceae and Poaceae species with different photosynthetic types.

## Results

### Taxonomic occurrence of $C_4$ species

There are 16 vascular plant families in which  $C_4$  photosynthesis occurs: 2 belong to Monocotyledoneae (Poaceae, Cyperaceae); and 14 to Dicotyledoneae (Acanthaceae, Aizoaceae, Amaranthaceae, Asteraceae, Boraginaceae, Caryophyllaceae, Chenopodiaceae, Euphorbiac-

<sup>a</sup> De Martonne aridity index,  $I=P/T+10$ , where  $P$  is annual precipitation (mm),  $T$  is average annual temperature (°C)

ae, Nyctaginaceae, Molluginaceae, Polygonaceae, Portulacaceae, Scrophyllariaceae, Zygophyllaceae). From the latest taxonomic data (Gubanov 1996) the flora of Mongolia consists of 2823 vascular species belonging to 128 families. Only representatives of Acanthaceae and Nyctaginaceae are absent in the Mongolian flora. We identified 80 species with  $C_4$  photosynthesis occurring in eight families: Amaranthaceae, Chenopodiaceae, Euphorbiaceae, Molluginaceae, Polygonaceae, Portulacaceae, Zygophyllaceae, and Poaceae (Tables 2, 3).

## Dicotyledonaeae

### Chenopodiaceae

Numerous  $C_4$  photosynthesis species in Chenopodiaceae were found in the subfamily Salsoloideae, tribes Salsoleae and Suaedeae, and in tribes Atripliceae and Camphorosmeae of the subfamily Chenopodioideae (Table 2). The Chenopodiaceae family ranks eighth amongst Mongolian flowering plants (Grubov 1996). There is a total of 91 chenopod species, and 41 of them, (c. 45%) exhibit  $C_4$  photosynthesis. The largest number of species with Kranz anatomy are in the Salsoleae tribe, where 26 of 29 are  $C_4$  photosynthesis species (Table 4). Sixteen species have a direct confirmation of  $C_4$  photosynthesis based on anatomy and biochemical tests (Table 2). Some species that were not experimentally verified as having  $C_4$  photosynthesis, belonging to *Anabasis*, *Climacoptera*, *Nanophyton* and *Petrosimonia*, are  $C_4$ , because these genera are derivatives of *Salsola* (Botschantzev 1969) in which all experimentally studied species demonstrate typical features of  $C_4$  photosynthesis (see references in Table 2). There are 11 *Salsola* species in the Mongolian flora, and 9 were identified as  $C_4$  species. *Salsola* mostly contains  $C_4$  plants, but a few are  $C_3$ , mainly shrubby forms (Pyankov

et al. 1993a, 1997; Akhani et al. 1997). The Kranz syndrome was found in seven species experimentally (Table 2). The photosynthetic type of two annual *Salsola* species was not identified (*S. ikonnikovii* and *S. rosaceae*). They that belong to the youngest and most progressive *Salsola* section of the genus *Salsola* (Botschantzev 1969) in which all studied species are  $C_4$  (Pyankov et al. 1992a, 1997; Akhani et al. 1997). There are two shrubby *Salsola* species, *S. abrobtanoides* and *S. laricifolia*, that are probably not  $C_4$ . *S. laricifolia* has a  $C_3$ -like  $\delta^{13}C$  value of  $-23.1\%$ . *S. abrobtanoides* was not studied, but it can be included as  $C_3$  based on its taxonomy. According to Botschantzev (1976) *S. abrobtanoides* belong to section *Coccosalsola*, subsection *Genistoides* together with two others, *S. webbi* and *S. genistoides*, in which  $C_3$  is well documented (Carolin et al. 1975; Winter 1981; Akhani et al. 1997; Pyankov et al. 1997).  $C_3$  photosynthesis in *Sympegma regelii* is well documented. It has a  $C_3$ -like centric non-Kranz-type anatomy named "sympegmoid" by Carolin et al. (1975). The vasculature is close to the Kranz salsoloid type, therefore Carolin et al. (1975) suggested that the sympegmoid may have originated from the salsoloid type with a reversion to  $C_3$  photosynthesis. We found high  $^{14}C$  incorporation into  $C_3$  primary photosynthetic products, but incorporation of label to primary  $C_4$  acids varied from 6 to 24% during 10 s of  $^{14}CO_2$  assimilation, somewhat high in comparison with typical  $C_3$  species (Black 1973).

Some genera of Chenopodiaceae that occur in Mongolia are known to have both  $C_3$  and  $C_4$  photosynthetic types, such as *Suaeda*, *Kochia*, *Atriplex*, and *Bassia*. There are ten species of *Suaeda* in the Mongolian flora (Gubanov 1996). We included two species in our list of  $C_4$  species, *S. arcuata* and *S. heterophylla*, based on previous results of early photosynthesis products and measurement of enzyme activities (Pyankov and Vakhrusheva 1989; Pyankov et al. 1992a). *S. arcuata* has  $C_4$ -like

values of <sup>13</sup>C/<sup>12</sup>C fractionation (Winter 1981; Akhani et al. 1997), which confirms the recent review of photosynthetic types in *Suaeda* (Fisher et al. 1997). It seems likely that eight other species, *S. corniculata*, *S. foliosa*, *S. glauca*, *S. kossinskyi*, *S. linifolia*, *S. prostrata*, *S. przhewalskii*, and *S. salsa* are C<sub>3</sub>. Some of them, *S. corniculata*, *S. glauca*, *S. linifolia* and *S. salsa*, show C<sub>3</sub>-like carbon fractionation values (Winter 1981; Akhani et al. 1997). In addition, taxonomic analysis of photosynthesis amongst *Suaeda* species show C<sub>3</sub> <sup>14</sup>CO<sub>2</sub> fixation for species belonging to the most primitive sections *Chenopodina* (syn. *Heterospermae*) (*S. corniculata*, *S. kossinskyi*, *S. prostrata*, *S. salsa*), and *Schanginia* (*S. glauca*, *S. linifolia*). There is some disagreement in identification of photosynthetic types; for instance, Gamaley (1985) included *S. corniculata* as a C<sub>4</sub> plant, but this may be an incorrect species identification. Experimental data are completely absent for *S. foliosa* and *S. przhewalskii*, so we have not included them in our list of C<sub>4</sub> species.

In the Camphorosmeae tribe C<sub>4</sub> species occur in *Camphorosma*, *Bassia*, *Kochia* and *Londesia*. *C. lessingi*, *L. eriantha* and almost all *Kochia* species have direct evidences of C<sub>4</sub> photosynthesis (Table 1). *K. krylovii* has no experimental data, but was included as a C<sub>4</sub> plant. All studied Asian species of *Kochia* demonstrate C<sub>4</sub> photosynthesis (Pyankov and Mokronosov 1993); and we agree with Carolin et al. (1975) that Eurasian *Kochia* species commonly have the Kranz syndrome.

For the two Mongolian *Bassia* species, one, *B. hyssopifolia*, is a typical C<sub>4</sub> plant with kochioid Kranz anatomy (Carolin et al. 1975; Gamaley 1985), C<sub>4</sub>-like <sup>δ</sup><sup>13</sup>C values (Table 1) and primary C<sub>4</sub> carbon metabolism (Pyankov and Vakhrusheva 1989). *B. dasyphylla* is a C<sub>3</sub> succulent with centric mesophyll structure (Gamaley and Shirevdamba 1988; Pyankov 1993) and a <sup>δ</sup><sup>13</sup>C value of -24.8‰.

Four of five *Atriplex* species were classified in the Kranz anatomy group. Mesophyll structure and photosynthesis enzyme activities were studied in *A. tatarica* and *A. sibirica* (syn. *A. centralasiatica*) (Pyankov et al. 1992a,

**Table 4** Occurrence of C<sub>3</sub> and C<sub>4</sub> species in Mongolian taxa of Chenopodiaceae

<b>Total</b>	<b>91</b>	<b>50</b>	<b>41</b>

1992b). *A. cana* is included based on leaf anatomy, <sup>δ</sup><sup>13</sup>C value, and primary photosynthetic products (Table 2). There is evidence of Kranz anatomy (Gamaley and Shirevdamba 1988) and a C<sub>4</sub>-like <sup>δ</sup><sup>13</sup>C value (Winter 1981) in *A. laevis*; but Akhani et al. (1997) found a C<sub>3</sub>-like <sup>δ</sup><sup>13</sup>C value, and it is a C<sub>3</sub> species according to Carolin et al. (1975). *A. fera* was not included in our C<sub>4</sub> list, because of lack of information about its type of carbon metabolism.

Akhani et al. (1997) reported a C<sub>4</sub>-like <sup>δ</sup><sup>13</sup>C value in *Axyris amarantoides*, which habitats in Mongolia (Gubanov 1996). However it seems likely, that this species is C<sub>3</sub>. Carolin et al. (1975) did not find Kranz anatomy in *A. amarantoides*, and *Axyris* is systematically very close to *Krashennikovia*, all representatives of which are typical xerophytes with a C<sub>3</sub> isopalisade leaf structure (Gamaley and Shirevdamba 1988).

The relationships between systematic groups of C<sub>4</sub> Chenopodiaceae and their Kranz anatomy and biochemical types now seem clear (Carolin et al. 1975; Voznesenskaja and Gamaley 1986; Glagoleva et al. 1992; Pyankov and Vakhrusheva 1989; Pyankov et al. 1992a, 1997). All species of *Atriplex* and *Suaeda* are NAD-ME. The species of Camphorosmeae (*Camphorosma*, *Kochia*, *Bassia*) are NADP-ME. But there are

different biochemical pathways for CO<sub>2</sub> metabolism among representatives of Salsoloideae. Annual plants belonging to section *Salsola* and derivative (*Halogeton*, *Micropeplis*), *Anabasis* and shrubs from section *Cocco-salsola* (*S. arbuscula*) and its derivative (*Haloxylon*, *Ijinia*) have the NADP-ME biochemical type. *Salsola* species of section *Malpigipila* (*S. gemmascens*, *S. passerina*), derivative species of sections *Belantera* (*Climacoptera*), *Caroxylon* (*Nanophyton*), and species of *Petrosimonia* genus are probably all NAD-ME photosynthetic types.

### Polygonaceae

*Calligonum* is a single genus in Polygonaceae that contains only C<sub>4</sub> species (Winter 1981; Voznesenskaja and Gamaley 1986; Pyankov et al. 1994). There are six *Calligonum* species found in Mongolia (Table 2). All species have a centric type of Kranz anatomy, similar in appearance to the salsoloid type (Voznesenskaja and Gamaley 1986). These species occur mainly in Gobian deserts; only *C. mongolicum* has a broader geographical distribution (Table 2).

### Other dicots

C<sub>4</sub> species were identified in five others dicotyledonous families (Table 2). There are mainly well-known naturalized species, e.g., *Amaranthus* (*Amaranthaceae*), *Portulaca oleraceae* (*Portulacaceae*), and the cosmopolitan species *Mollugo cerviana* (*Molluginaceae*) and *Tribulus terrestris* (*Zygophyllaceae*). We found a C<sub>4</sub>-like δ<sup>13</sup>C value in *Euphorbia mongolicum* (*Euphorbiaceae*). Voznesenskaja and Gamaley (1986) reported the C<sub>4</sub> syndrome in *E. humifusa* from Mongolia; but our δ<sup>13</sup>C determination of -26.3, is a C<sub>3</sub>-like value.

## Monocotyledoneae

### Poaceae

Grasses include 250 species and the *Poaceae* family is third in abundance in the Mongolian flora (Gubanov 1996). Identification of C<sub>4</sub> grass species was on the basis of experimental studies of Kranz anatomy and δ<sup>13</sup>C values plus published data (Table 2), and there are strong taxonomic relationships in grasses (Hattersley and Watson 1992). Based on these characters we identified 25 grasses with the Kranz syndrome, i.e., 10% of total *Poaceae*. We found species with the C<sub>4</sub> syndrome in five tribes Andropogoneae, Paniceae, Aristideae, Arundinelleae, and Cynodonteae. A majority of C<sub>4</sub> grasses, 16 species, belong to Cynodonteae and have NAD-ME or PEP-CK metabolism. Species with NADP-ME are comparatively few, and tribes Andropogoneae, Aristideae, and Arundinelleae consist of only single species. The representatives of Paniceae (*Echinochloa*, *Panicum*, and *Setaria*) are naturalized species and occur mainly in annually disturbed regions and oases. Other C<sub>4</sub> annuals with an aspartate-forming type of metabolism, NAD-ME or PEP-CK, i.e., *Chloris virgata*, *Enneapogon*, and *Eragrostis* species are cosmopolitan, and their appearance in natural ecosystems very strongly depends on precipitation. Thus, only a few C<sub>4</sub> grasses, such as species of *Cleistogenes*, *Aristida*, *Aeluropus*, *Tragus*, and *Eragrostis*, are important in natural ecosystems.

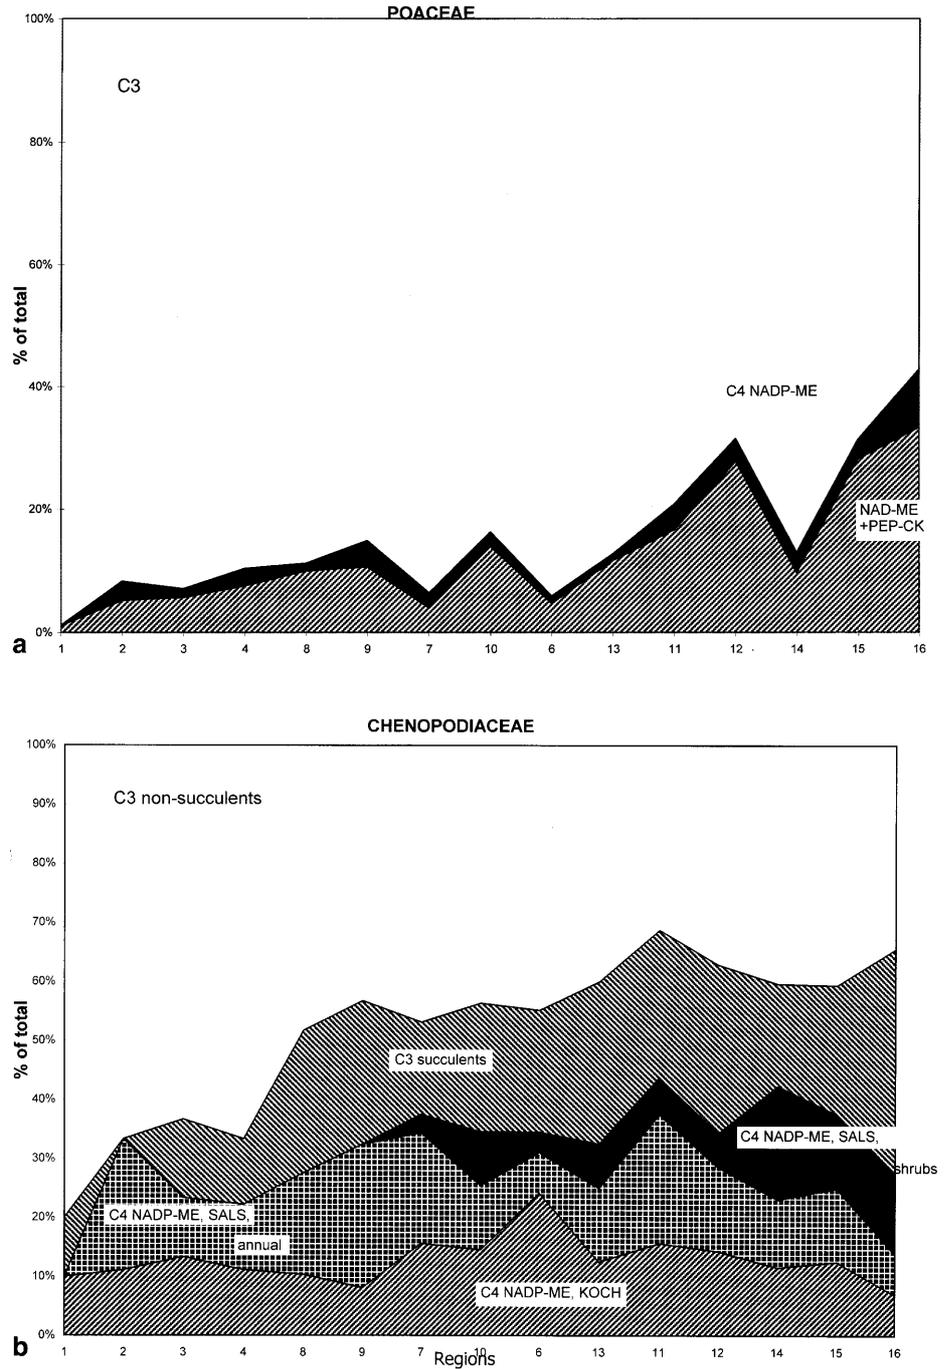

### Cyperaceae

In the Mongolian flora, the *Cyperaceae* family includes 127 species belonging to 27 genera (Gubanov 1996); but no C<sub>4</sub> species were identified in Mongolia.

**Table 5** Distribution of Chenopodiaceae species with different types of photosynthesis and life forms in botanical-geographical regions of Mongolia

**Fig. 3** Proportions of **a** Poaceae and **b** Chenopodiaceae families with different types of photosynthesis, structural and biochemical features of  $C_4$  syndrome, and life forms, along the aridity gradient in botanical-geographical regions of Mongolia (*SALS* and *KOCH* are salsoid and kochioid types of Kranz anatomy, respectively). Region 5 was excluded

Patterns of climatic distribution for  $C_4$  Chenopodiaceae and Poaceae

*Chenopodiaceae*

Table 5 summarizes our data on the distribution and relative abundance of Chenopodiaceae species with different photosynthetic types in the botanical-geographical regions of Mongolia. In general, we found increasing numbers and percentage of  $C_3$  and  $C_4$  chenopods along an increasing warm and aridity gradient. The number of  $C_4$  species varied from 1 (Khubsugul) to 31 (Dzungarian

Gobi). The  $C_4$  percentage increased along an aridity and temperature gradient, but the highest absolute and relative abundance of the  $C_4$  chenopods, 31 (50.8%) was found in Dzhungarian Gobi. In other southern hot and arid deserts, Transaltai and Alashan Gobi, chenopod numbers were lower, and consisted of only 10  $C_4$  species (32.3% of Chenopodiaceae) in Alashan Gobi.

The proportions of chenopods with different types of  $CO_2$  fixation and structural and biochemical subtypes of  $C_4$  also changed along the temperature and aridity gradient (Fig. 3). The relative abundance of non-succulent  $C_3$  chenopod species decreased from cool moist to warm de-

**Table 6** Correlation coefficients of  $s$  between occurrence of  $C_4$  species in Chenopodiaceae (*CH*) and Poaceae (*POA*) and climatic variables in Mongolia. Correlations  $>0.50$  are significant at  $P<0.05$ 

Plant group	Aridity index (de Martonne)	Sum of temperatures $>10^{\circ}\text{C}$	Annual precipitation (mm)	Annual average temperature ( $^{\circ}\text{C}$ )	July average temperature ( $^{\circ}\text{C}$ )

sert regions. In general, the percentage of  $C_4$  species of Chenopodiaceae positively correlated with increasing of aridity (or negative with aridity index) in each district (Table 6),  $r=-0.74$ ,  $P<0.05$ . Temperature parameters, i.e., the sum of effective temperatures or average annual or July temperatures were positively, but not significantly, correlated with the relative abundance of  $C_4$  Chenopodiaceae (Table 6).

The chenopods with  $C_4$   $\text{CO}_2$ -fixation have different types of Kranz anatomy, biochemical subtypes, and life forms (Table 2). There are four types of Kranz anatomy: atriplexoid, suaedoid, kochioid, and salsoloid, and two biochemical subtypes, NAD-ME and NADP-ME. Plants with salsoloid Kranz anatomy included both biochemical variants plus two contrasting groups with different life forms – shrubs and annuals. We hypothesized that various groups of  $C_4$  Chenopodiaceae responded differently to environmental variables. This hypothesis could be tested by analyzing each group of Chenopodiaceae in relation to climatic variables, but there were not enough  $C_4$  *Atriplex* and *Suaeda* species for this analysis. We therefore studied the climatic patterns in Camphorosmeae and the main groups of Salsoleae, which contain the largest number of  $C_4$  chenopods. We found a different composition of groups along the aridity gradient (Fig. 3, Table 5). Large shrubs with a salsoloid type of assimilation organs and NADP-ME biochemical subtypes, such as *Haloxyton*, *Iljinia*, *Salsola arbuscula*, and semishrubs of genus *Anabasis*, appeared only in dry and hot regions with an aridity index near 10 or less, and occurred mainly in Gobian deserts. Their relative abundance was significantly and positively correlated with aridity ( $r=0.69$ ) and the average annual temperature ( $r=0.69$ ), and negatively with annual precipitation ( $r=-0.75$ ).

The annuals, *Salsola* NADP-ME species, are common in all regions (Fig. 3), but their percentages show no correlation with the main climatic variables in Mongolia (Table 6). Species with a kochioid type of Kranz anat-

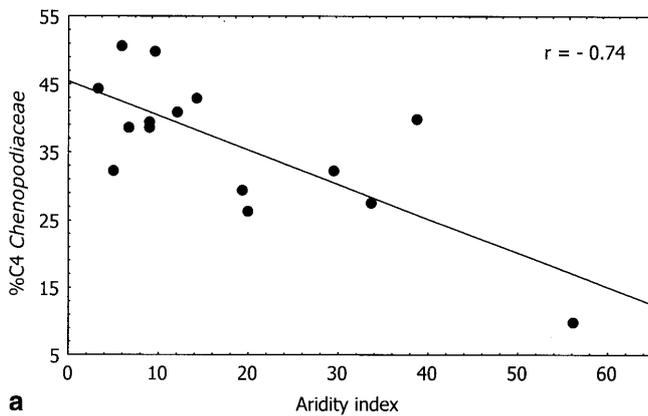

omy, which include semishrub and annual species, occur over a broad climatic range, and their relative abundance is maximum in dry, but not very hot areas (Fig. 3). The percentage of  $C_4$  species of this group was positively and significantly correlated with aridity ( $r=0.57$ ), but not with temperature parameters. The correlation coefficient between aridity and percentage of  $C_4$  species in this group is significantly lower than in the group of NADP-ME shrubs and semishrubs with a salsoloid type of mesophyll structure. The highest coefficient between aridity and percentage of  $C_4$  species was found for a group, of  $C_4$  NADP-ME shrubs with a salsoloid anatomy and  $C_3$  succulents combined, that consisted of *Halocnemum*, *Kalidium*, *Salicornia*, *Salsola*, *Suaeda*, *Sympegma*. The relative abundance for this group of combined  $C_3$  and  $C_4$  succulents correlated best with aridity ( $r=0.97$ ) (Table 6, Fig. 4). The correlation with temperature was also high ( $r=0.80$ ), but lower than that for aridity. Thus chenopods with  $C_4$  photosynthesis and  $C_3$  succulents are favored in areas with a hot, dry climate.

#### Poaceae

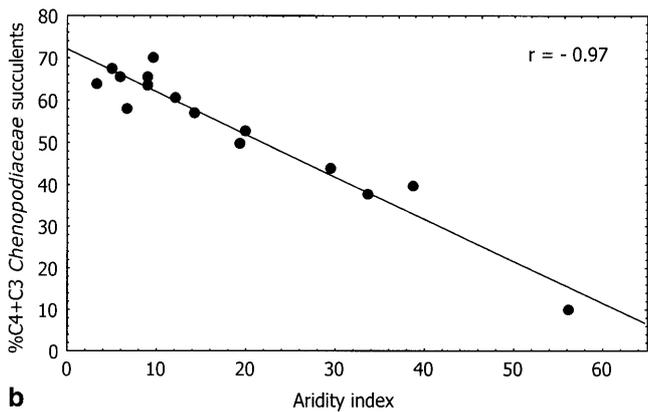

There is considerable variation in the frequency of  $C_3$  and  $C_4$  grasses in different Mongolian regions (Table 7). We found different patterns of distribution for grasses with  $C_3$  versus  $C_4$  types of photosynthesis. The highest absolute number of  $C_3$  grasses, 80–140 species per district, was detected in areas with cool and moist climates in northern and central mountain regions (Khangai, Khentei, Mongolian Altai, Depression of the Great Lakes), and in drier and warmer eastern regions (Middle Khalkha, East Mongolia, Gobi Altai). The highest total number of  $C_4$  grasses and percentages were in southern districts – Valley of Lakes, Transaltai, Alashan and East Gobi (Table 7). In semiarid steppe and semidesert areas the percentage of  $C_4$  grasses was between 10 and 20%.

b

**Fig. 4** Relationship between the occurrence of **a** C<sub>4</sub> Chenopodiaceae species, and **b** C<sub>3</sub>+C<sub>4</sub> succulent Chenopodiaceae species, and aridity index in Mongolia

Temperature was the climatic variable which showed the strongest correlation with the percent of C<sub>4</sub> grasses ( $r=0.90$ ) (Table 6, Fig. 5). Only one C<sub>4</sub> cosmopolitan grass species, *Eragrostis minor*, occurred in the northern district (Khyubsugul), where the July average minimum temperature is 5.6°C. In the Khangai region, where the

a

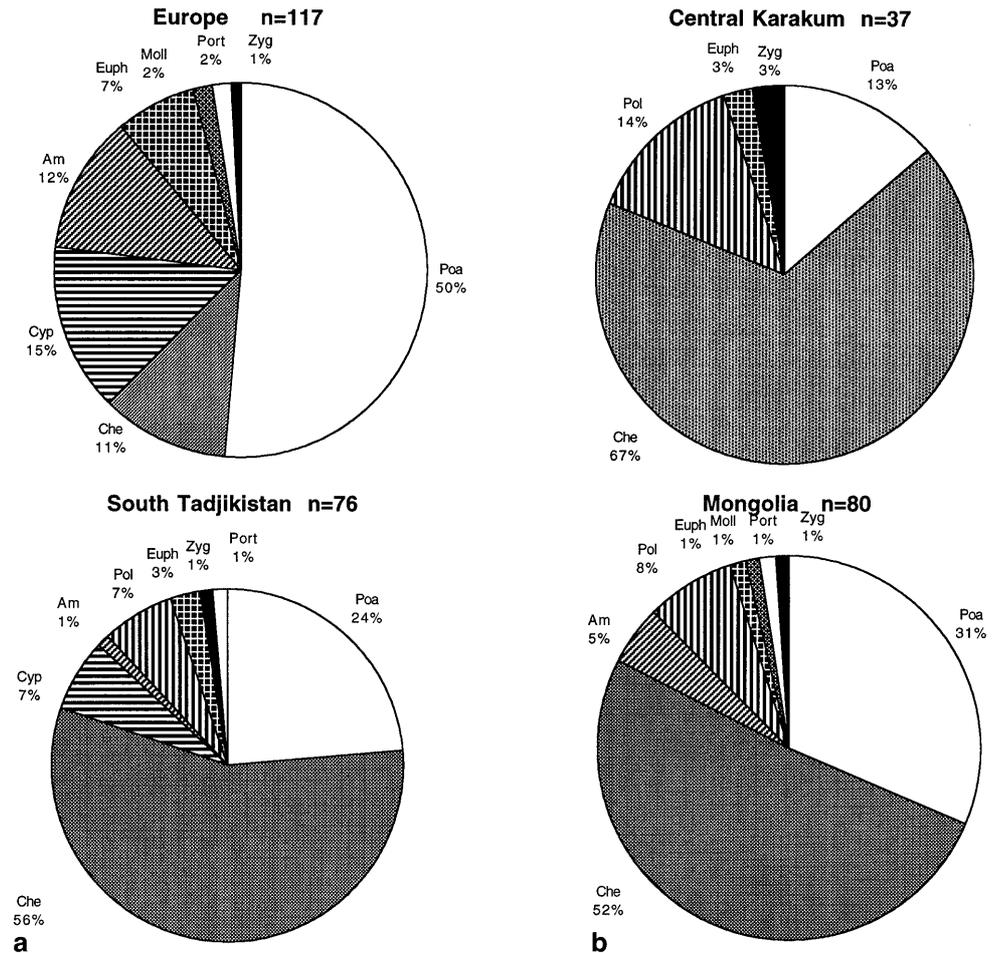

b

**Fig. 5** Relationship between the abundance of C<sub>4</sub> Poaceae and **a** normal July minimum temperature and **b** the annual sum of temperatures over 10°C in Mongolia

average July minimum temperature was 9°C, we identified four grasses with Kranz anatomy. The regression line of percentage C<sub>4</sub> Poaceae versus temperature (Fig. 5) shows a decrease in the relative abundance C<sub>4</sub> grasses to zero when the July normal minimum temperature is about 7.5°C. The distribution of C<sub>4</sub> grass species was

**Fig. 6** Taxonomic spectrums of  $C_4$  taxa in different Eurasian regions: Europe (Mateu-Andres 1992); Central Karakum desert, Turkmenistan (Pyankov et al. 1986); South Tadjikistan (Pyankov and Molotkovskii 1992, 1993); and Mongolia (families: *Che* Chenopodiaceae, *Poa* Poaceae, *Pol* Polygonaceae, *Euph* Euphorbiaceae, *Port* Portulacaceae, *Zyg* Zygophyllaceae, *Am* Amarantaceae;  $n$  total  $C_4$  species number, % percent of  $C_4$  taxa out of total  $C_4$  species)

highly and positively correlated with all temperature parameters. The highest correlation ( $r=0.90$ ) was with the sum of temperatures over  $10^{\circ}\text{C}$ , i.e., with the total amount of warmth in a region. Grasses with  $C_4$  photosynthesis normally habitats in regions with a sum of temperatures over  $10^{\circ}\text{C}$  that exceeds  $1200^{\circ}\text{C}$ .

The correlation analysis shows some differences in the climatic preferences of  $C_4$  grasses of different biochemical groups. Species belonging to aspartate-forming types of  $C_4$  photosynthesis (NAD-ME and PEP-CK), mainly native grasses, are more closely correlated with temperature than NADP-ME species, which belong to the weedy naturalized flora (*Echinochloa* and *Setaria*) (Table 6).

Patterns of climatic distribution for  $C_4$  plants in other families

The plants of genus *Calligonum*, Polygonaceae, are the most interesting of the other families. All six species of this genus occur in very arid deserts (Dzhungarian, Transaltai, and Alashan Gobi). Only *C. mongolicum* has a broad distribution in the Gobian deserts that occur in more northern regions, including eastern Mongolia and the Depression of the Great Lakes. The climatic range of *Calligonum* species is similar to that of  $C_4$  shrubby

Chenopodiaceae species, and depends upon aridity and warm temperatures.

Other  $C_4$  dicotyledonous species, excluding *Euphorbia mongolicum*, are weedy or cosmopolitan species that occur in many botanical-geographical districts; but their habitat is connected with annually disturbed areas and oases, i.e., with human activities (Table 2).

## Discussion

Our studies show a "Turanian" type of  $C_4$  species composition in Mongolia with a strong dominance by Chenopodiaceae, which make up over 50% of the total  $C_4$  species. Turanian deserts are arid places with hot continental climates that occupy the region of Turanian lowland, limited by the Caspian sea to the west, and the Pamirs and Tien-Shan mountains to the south and south-sast (Lavrenko and Nikolskaja 1963). Turanian type deserts, such as the Karakum and Kyzylkum, are characterized by a strongly continental climate with hot dry summers and cold winters. These deserts contain different kinds of soil substrates (sand, clay, rocky surfaces, salt-marshes) with a very strong dominance of  $C_4$  plants in the Chenopodiaceae family (Pyankov et al. 1986; Pyankov and Mokronosov 1993).

The relative abundance of C<sub>4</sub> grasses and chenopod species in Mongolia is close to the taxonomic composition of C<sub>4</sub> plants found previously in Central Karakum deserts (Pyankov et al. 1986) and South Tadjikistan (Pyankov and Molotkovskii 1992, 1993) (Fig. 6). Monocots with Kranz anatomy are very few in Mongolia. Only 25 species are present, including about 10 naturalized and cosmopolitan species in *Chloris*, *Echinochloa*, *Eragrostis*, *Panicum*, and *Setaria*. There are no C<sub>4</sub> Cyperaceae. This composition is very different from the desert and semidesert regions in Australia (Hattersley 1983), South Africa (Vogel et al. 1978; Schulze et al. 1996), North Africa (Batanouny et al. 1988), and North America (Ehleringer et al. 1997) where C<sub>4</sub> grasses are dominants, and chenopods with C<sub>4</sub> photosynthesis are not abundant. Even in Europe, about 50% of total C<sub>4</sub> species are Poaceae, while Chenopodiaceae make up only 11% (Mateu Andres 1992). The total numbers of C<sub>4</sub> families in Mongolia is also low, and four of the eight families (Amaranthaceae, Molluginaceae, Portulacaceae, and Zygo-phylloaceae) contain only weedy and cosmopolitan species. Thus, the native Mongolian C<sub>4</sub> flora presumably formed from representatives of three main families: Chenopodiaceae, Poaceae, and Polygonaceae, which together make up about 90% of the total number of C<sub>4</sub> photosynthesis species (Fig. 6).

The percentage of C<sub>4</sub> species in the total Mongolian flora is only about 3.5%. However if we calculate the percentage of species that occur in Gobian deserts (about 550 species) (Vostokova et al. 1995), there are nearly 14.5% C<sub>4</sub> species, quite comparable with the figures for hot Turanian deserts, where about 15–17% of total species are C<sub>4</sub> (Pyankov et al. 1986; Pyankov and Molotkovskii 1993). Hot Turanian deserts are very rich in absolute numbers of C<sub>4</sub> Chenopodiaceae species. There are over 200 chenopods with C<sub>4</sub> photosynthesis (not including *Atriplex*) in the arid regions of the former Soviet Union (Pyankov and Mokronosov 1993). They also are broadly distributed in desert regions of the Near and Middle East, the Arabian peninsula and in northern Africa (Shomer-Ilan et al. 1981; Ziegler et al. 1981; Winter 1981; Akhani et al. 1997). Similar proportions of C<sub>4</sub> plants and patterns of climatic distribution in those regions is likely connected with the common origin of the flora in these regions. According to Lavrenko (1962) these areas all belong to an Afro-Asian or Saharo-Gobian desert region characterized by common features of their desert flora, the first of which is a high abundance of Chenopodiaceae species.

The physiological background for the broad species distribution of Salsoleae in Afro-Asian desert regions is connected with their C<sub>4</sub> type of photosynthesis. Over 300 species of Salsoleae have been studied in those regions, but a C<sub>3</sub> type of photosynthesis was found only in about 6 *Salsola* species and *Sympegma regelii* (Winter 1981; Pyankov et al. 1993a, 1993b, 1997; Akhani et al. 1997). Probably this abundance of C<sub>4</sub> is related to known traits such as a high water use efficiency, higher photosynthetic temperature optimum, and a stable quantum yield at

high temperatures (Black 1971, 1973; Ehleringer 1978; Ehleringer and Monson 1993; Ehleringer et al. 1997).

The preponderance of C<sub>4</sub> chenopods over grasses in Asian continental deserts is connected with a high resistance to drought. All C<sub>4</sub> chenopods of tribes Salsoleae, Suaedeae, and Camphorosmeae are succulents with water-storage tissue occupying the central part of cylindrical leaves, and in many species there is an additional layer of hypodermal cells under the epidermis to lower H<sub>2</sub>O loss (Carolin et al. 1975; Shomer-Ilan et al. 1981; Gamaley 1985; Voznesenskaja and Gamaley 1986). Usually the rate of transpiration in C<sub>4</sub> chenopods is significantly lower than in C<sub>4</sub> grasses. For instance, the average transpiration rates of *Salsola passerina*, *Haloxylon ammodendron* and *Anabasis brevifolia* in Gobian deserts were in the range 150–350 mg H<sub>2</sub>O g fresh mass<sup>-1</sup> h<sup>-1</sup>; but in a C<sub>4</sub> grass, *Cleistogenes songorica*, the range was 200–800 mg H<sub>2</sub>O g fresh mass<sup>-1</sup> h<sup>-1</sup> (Bobrowskaja 1991). In the Karakum desert, the maximum values of transpiration recorded were about 200–700 mg H<sub>2</sub>O g fresh mass<sup>-1</sup> h<sup>-1</sup> in *Haloxylon aphyllum* and *Salsola richterii*; but 590–1100 mg H<sub>2</sub>O g fresh mass<sup>-1</sup> h<sup>-1</sup> in the Kranz grass *Stipagrostis karelinii*. The transpiration rates of *Haloxylon aphyllum* and *Salsola richterii* were 4–18 times lower than evaporation from a water surface, while the rate for *Stipagrostis karelinii* was only 3–9 times lower (Sveshnikova 1972). C<sub>4</sub> chenopod succulents are also characterized by high osmotic pressures and leaf suction forces that were about twice those in desert C<sub>4</sub> grasses (Sveshnikova 1972; Bobrowskaja 1991). In general these traits provide stable water regimes and little water deficit in assimilation organs of succulent chenopods, particularly shrubs as from *Haloxylon*, *Salsola*, and *Iljinia* that never decrease their water contents to lethal levels (Sveshnikova 1972; Bobrowskaja 1985, 1991). Many chenopods are also halophytes, particularly species with NAD-ME biochemistry (Pyankov and Vakhrusheva 1989; Glagoleva et al. 1992; Pyankov et al. 1992a; Fisher et al. 1997), and can grow on soils with salinity up to 2–3.5% and accumulate up to 30–47% mineral content (Kolchevskii et al. 1995). Therefore the combination of C<sub>4</sub> photosynthesis with succulence, water relations, and salt resistance in Chenopodiaceae allow these plants to occupy a broad range of ecological conditions in very arid environments.

Some succulent Chenopodiaceae species with C<sub>3</sub> photosynthetic type, for instance *Sympegma regelii*, are dominants of true deserts and are broadly distributed in all desert regions, particularly western Mongolia (Vostokova et al. 1995). Two C<sub>3</sub> *Salsola* species, *S. laricifolia* and *S. abrotanoides*, occur in arid regions, and *S. laricifolia* occurs in all Gobian deserts (Gubanov 1996). Other C<sub>3</sub> succulents, such as species of *Kalidium*, *Salicornia*, *Suaeda*, *Halocnemum*, occur preferentially in moist saline soils, where high aridity and water evaporation are common, in southern Mongolia. Hence the abundance of succulent chenopods increases with aridity in Mongolia, where C<sub>4</sub> species preferentially occupy dry habitats and C<sub>3</sub> species are commoner in moist saline habitats. Leaf succulence is

an effective mechanism in desert sites with limited water supply both for  $C_4$  and  $C_3$  plants. Chenopodiaceae as a whole is the principal family in desert regions of Asia and North Africa (Lavrenko 1962). We speculate that the broad distribution of chenopods in these desert regions and their adaptations to arid conditions were the physiological basis for the origin of  $C_4$  photosynthesis.

We also found that the proportion of  $C_4$  chenopods changed with different Kranz anatomy, biochemical types, and life forms along the aridity gradient (Fig. 3). Perennial shrubs with a salsoloid type of mesophyll and NADP-ME biochemistry, such as *Anabasis brevifolia*, *Iljinia regelii*, *Salsola arbuscula*, *Haloxylon ammodendron*, mainly occur in Gobian deserts and dominate the plant cover (Vostokova et al. 1995). *S. arbuscula* and *I. regelii* occur only in deserts with extra arid climate with annual precipitation about 50–70 mm, and less than 10 mm in some years (Vostokova et al. 1995). Those plants are characterized by low transpiration rate, with a range of 100–400 mg  $H_2O$  g fresh mass<sup>-1</sup> h<sup>-1</sup>. The variation in water content of assimilation organs in *H. ammodendron* and *I. regelii* during the hot days of summer is no more than 5–7%, which is very far from the lethal water deficit for these species of 43.8 and 38.6% respectively (Bobrowskaja 1991). These plants are large, even tree-like, shrubs with a deep root system that reaches underground water supplies. Once again the combination of a water-use efficient type of  $CO_2$  fixation ( $C_4$  type) with water storage (succulence) and effective collection of ground water with the shrub or tree life form allows these plants to grow and survive in very arid deserts. Despite a relatively low species number, their contribution to the productivity of Gobian deserts is very high, 30–90% of total ecosystem plant biomass (Vostokova et al. 1995).

Amongst other  $C_4$  dicots only the Polygonaceae representative *Calligonum* is a major component of natural ecosystems in Mongolia. The climatic distribution pattern of *Calligonum* is similar to that of shrubs with NADP-ME metabolism and salsoloid assimilation organ anatomy. All *Calligonum* species, besides *C. mongolicum* and *C. pumilum*, occur only in the arid desert regions of southern Mongolia (Table 2). The assimilation organs in *Calligonum* are the green shoots, which have a centric mesophyll structure similar in appearance to the salsoloid Kranz type (Voznesenskaja and Gamaley 1986). All species of *Calligonum* studied have NAD-ME biochemistry (Pyankov et al. 1994). *Calligonum* species in the hot deserts of Mongolia make up only about 20% of the total species number (Soskov 1989). Transpiration rate in *Calligonum* species is low and similar to that of desert  $C_4$  large chenopod shrubs, such as *Haloxylon* and *Salsola richteri* (Sveshnikova 1972). Hence it is clear that  $C_4$  dicots with similar anatomy and life form, even though they belong to different taxa, have similar climatic distribution patterns.

Plants with a kochioid type of Kranz anatomy, e.g., *Bassia*, *Camphorosma*, *Kochia*, and *Londesia*, grow over a broad climatic range with a maximum abundance in steppe and semidesert regions (Fig. 3). This group shows little correlation with aridity index ( $r=-0.57$ ) or tempera-

ture sum ( $r=0.17$ ). Only two semishrub species, *Kochia prostrata* and *Camphorosma lessingii*, make significant contributions to productivity in a limited number of semi-desert and arid mountain areas. These annual species have little ecological importance in Mongolian ecosystems. Thus, plants with kochioid type anatomy are not part of the typical desert vegetation; rather they are adapted to drought and to a broad range of temperature conditions, particularly to cold.

Temperature is the main factor that controls the abundance of  $C_4$  grasses in Mongolia,  $r=0.90$ ,  $P<0.01$  (Table 6, Fig. 5). The spread of grasses with Kranz anatomy to the north is limited by the normal average July minimum temperature of 7.5°C or a 1200°C sum of temperatures over 10°C (Fig 5, Table 7). Geographically this limit is close to 50°N. Plants with NADP-ME biochemistry are mainly weedy naturalised species, whose habitats are mainly associated with disturbed areas, agricultural fields, and oases in desert regions. The absolute number and percentage of NADP-ME grasses are similar in steppe and desert regions in Mongolia (Table 7) and correlate poorly with climatic parameters in comparison with the percentage of  $C_4$  in Poaceae (Table 6). The relative abundance of aspartate-forming grasses of NAD-ME and PEP-CK biochemical subtypes, belonging to the Cyndontae tribe, was highly and positively ( $r=0.89$ ,  $P<0.01$ ) correlated with temperature. The absolute number of aspartate-type grasses is highest in steppe regions of East Gobi, the Depression of the Great Lakes, and in mountain regions of southern Mongolia, as in Gobi Altai. Some species of that group, such as *Cleistogenes songorica*, are co-dominant in desert steppes with annual precipitation about 100 mm (Vostokova et al. 1995). In true deserts, where average annual precipitation is 50–70 mm, and sometimes less than 10 mm, e.g., in Gobian deserts, grasses occur mainly in oases and make no regular contribution to the natural vegetation. Large perennial thermophilic grasses, like *Stipagrostis karelinii* and *S. pennata*, that have NADP-ME and are summer dominants in the hot, sandy Karakum and Kyzylkum deserts (Voznesensky 1977), are absent in Mongolia.

The  $C_4$  flora of Mongolia is the most cold-resistant variant of Turanian desert vegetation, indeed it forms part of the northern boundary of  $C_4$  plant distribution. In Mongolia 13 Chenopodiaceae species with  $C_4$  photosynthesis, from the genera *Atriplex*, *Halogeton*, *Kochia*, and *Suaeda*, are common, with  $C_4$  plants occurring in the Pamir mountains at elevations from 1700 to 4500 m (Pyankov 1993; Pyankov and Mokronosov 1993). These make up about 70% of the Pamirian mountain flora with  $C_4$  photosynthesis. Eight species with  $C_4$  photosynthesis occur in the dry and cool mountain desert of the East Pamirs around 3600–4500 m, and four of those species in the genera *Atriplex*, *Halogeton*, *Salsola*, and *Kochia* (Pyankov 1993) are common among Mongolian plants. These species occur near the summer snow line (4600–4800 m) and at the limit of everyday night frost (4100–4200 m); therefore they are amongst the most cold-resistant plants with  $C_4$  photosynthesis known.
